Highlights

- The most-sensitive aquatic endpoint correlates with testing effort at $\rho = -0.75$
- Depth equalisation removes 40–48% of it: an extreme-order-statistic artefact
- Swapping only the endpoint raises rank transfer by $\Delta\rho = +0.32$ on 58 PFAS
- An effort-stable endpoint narrows the 90% prediction interval from 10.5 to 4.5
- No untested PFAS clears at a stringency-matched hazard threshold even so
